We report a systematic investigation of Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ based on transport and $^{75}$As NMR measurements, and establish the electronic phase diagram. We demonstrate that doping progressively suppresses the uniform spin susceptibility and low frequency spin fluctuations. The optimal superconducting phase emerges at $x_c \approx 0.08$ when the tendency toward spin ordering completely diminishes. Our findings point toward the presence of a quantum critical point near $x_c$ between the SDW (spin density wave) and superconducting phases.

KEYWORDS: iron pnictide superconductor, high temperature superconductivity, NMR, quantum criticality

DOI: 10.1143/JPSJ.78.013711

The recent discovery of iron-pnictide high $T_c$ superconductors$^{1-6}$ poses a new intellectual challenge in condensed matter physics. Although the superconducting mechanism remains unknown, it has become apparent that iron-pnictides share remarkable similarities with high $T_c$ cuprates: the undoped parent phases LaFeAsO and BaFe$_2$As$_2$ have FeAs square-lattice sheets, and itinerant electrons in these layers undergo antiferromagnetic long range order (AFLRO) below modest temperatures, $T_{SDW} \sim 140 \, \text{K}^{7,8}$; electron or hole doping suppresses the AFLRO and induces superconductivity. There exist clear dissimilarities, too. For example, all five 3d orbitals of Fe atoms contribute to the multiple Fermi surfaces, hence to superconductivity, in iron-pnictides.$^{10,11}$ In contrast, only the Cu 3d$_{x^2-y^2}$ orbital plays a role in cuprates. Furthermore, substitution of Co atoms into Fe sites of the parent phases results in electron doping and induces superconductivity$^{12-14}$ without creating localized moments,$^{15}$ while Zn$^{2+}$ ions doped into Cu$^{2+}$ sites induce localized moments and destroy superconductivity in cuprates. Sorting out these similarities and dissimilarities may lead us to an understanding of the mechanism of high $T_c$ superconductivity in iron-pnictides as well as in cuprates.

In this letter, we utilize transport and NMR techniques to probe the evolution of the electronic properties of Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ single crystals from the undoped SDW phase ($x = 0$ with $T_{SDW} = 135 \, \text{K}$), undoped SDW phase ($x = 0.02$ with $T_{SDW} = 100 \, \text{K}$), and $x = 0.04$ with $T_{SDW} = 66 \, \text{K}$), optimally doped superconducting phase ($x = 0.08$ with $T_c = 22 \, \text{K}$), to the slightly overdoped regime ($x = 0.105$ with $T_c = 15 \, \text{K}$). We establish the electronic phase diagram which has a quantum critical point near the optimum concentration $x_c \sim 0.08$, and explore the possible relation between paramagnetic spin fluctuations and the mechanism of superconductivity. From NMR Knight shift and spin–lattice relaxation rate measurements, we show that electron doping progressively suppresses the uniform spin susceptibility $\chi_{\text{spin}}$ and low frequency spin fluctuations. The optimally doped superconducting phase emerges at $x_c \sim 0.08$ as soon as doped electrons completely suppress the tendency toward AFLRO.

We grew single crystals of Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ from FeAs flux$^{13}$ and determined the actual Co concentration $x$ by energy dispersive X-ray spectroscopy (EDS). The $x = 0.08$ sample is the same specimen as the one we previously studied and labeled as $x = 0.1$,$^{13,15,16}$ and has the nominal starting composition of $x = 0.1$. The bulk characterization of the $x = 0.04$ and 0.08 crystals is discussed elsewhere.$^{13,16}$ We carried out NMR measurements using standard pulsed NMR techniques for aligned single crystals with the total mass of ~2 to ~20 mg. We measured the frequency dependence of the spin–lattice relaxation rate divided by temperature $T$, 1/$T_1$, within a single NMR line by integrating the FFT signals for an appropriate frequency range. AC resistivity measurements were performed with the standard four probe method. We define the critical temperature $T_{SDW}$ of AFLRO based on the maximum negative slope of $\rho_{ab}$, while $T_c$ was determined by SQUID measurements. We summarize the resistivity data in Fig. 1, and the electronic phase diagram of $T_{SDW}$ and $T_c$ in Fig. 2.

In Fig. 3, we present typical $^{75}$As NMR linewidths of the $I_x = 1/2 \rightarrow +1/2$ transition at 175 K obtained by FFT of the spin echo envelope measured in a fixed magnetic field of $B_{\text{ext}} \sim 7.7 \, \text{T}$ applied along the crystal $c$-axis. For clarity, we converted the horizontal axis of the NMR resonance frequency $f$ to the NMR Knight shift, $K$, based on the following relation,$^{17}$

$$f = (1 + K)\gamma_B B_{\text{ext}},$$

where $\gamma_B$ is the nuclear gyromagnetic ratio, and

$$K = K_{\text{spin}} + K_{\text{chem}},$$

$$K_{\text{spin}} = \frac{\Delta hf}{N_A \mu_B} \chi_{\text{spin}}.$$  

The Knight shift $K$ consists of two separate contributions. The first term in eq. (2a), $K_{\text{spin}}$, is the spin contribution, and proportional to the local spin susceptibility along the $c$-axis, $\chi_{\text{spin}}$, as defined in eq. (2b). The second term in eq. (2a), $K_{\text{chem}}$, is a temperature-independent background term (the chemical shift), and is not related to $\chi_{\text{spin}}$. From the measurement at 4.2 K in the superconducting state below $T_c$ of the $x = 0.08$ sample, we estimate $K_{\text{chem}} = 0.224\%$.
along the c-axis.\(^{15}\) \(A_{\text{hf}} = 18.8\ \text{kOe}/\mu_B\) in eq. (2b) represents the hyperfine interaction along the c-axis between the observed \(^{75}\text{As}\) nuclear spin and electron spins,\(^{18}\) and \(N_A\) is the Avogadro’s number.

We summarize the \(T\) and \(x\) dependences of the center of gravity of \(K\) in Fig. 4. Equation (2b) implies that a change in the spin contribution to the Knight shift by the amount of \(\Delta K_{\text{spin}} = 0.0339\%\) corresponds to that of \(\Delta \chi_{\text{spin}} = 1 \times 10^{-4} \text{ emu/mol-Fe}\) along the c-axis. We show the conversion on the right vertical axis of Fig. 4. The magnitude of \(\chi_{\text{spin}}\) is comparable to that of \(\text{LaFeAsO}_0.09\text{Fe}_0.1\).\(^{16}\) Notice that the origin on the right axis, \(\chi_{\text{spin}} = 0\), is matched with the temperature independent background contribution \(K_{\text{chem}} = 0.224\%\). Figure 4 represents the first successful measurements of the intrinsic behavior of \(\chi_{\text{spin}}\) for a broad range of concentrations of iron pnictides.

We notice two striking features in Fig. 4. First, doped electrons suppress \(\chi_{\text{spin}}\). We recall that doped holes enhance \(\chi_{\text{spin}}\) in high \(T_c\) cuprates,\(^{20}\) and the enhancement is interpreted as a consequence of the suppression of some energy scale with doping, such as the effective spin–spin exchange interaction \(J\) or spin pseudo-gap \(\Delta_{Q}\).\(^{20,21}\) If we interpret the results of Fig. 4 in an analogous manner, our results imply that the energy scale increases with doping in \(\text{Ba(Fe}_{1-x}\text{Co}_x)\text{As}_2\). Second, the \(T\) dependence of \(\chi_{\text{spin}}\) is qualitatively similar in the paramagnetic state of all samples from undoped antiferromagnet (\(x = 0\)) to the slightly overdoped superconductor (\(x = 0.105\)); \(\chi_{\text{spin}}\) decreases roughly linearly for all samples below 300 K, then begins to level off below \(\sim 100\) K toward \(T_c\) in the superconducting samples with \(x \geq 0.08\). \(\rho_{ab}\) also shows a \(T\)-linear behavior in the same temperature regime below \(\sim 100\) K, as initially reported for \(x = 0.08,13,16\). That is, the high \(T_c\) superconductivity of iron pnictides arises from a novel electronic state with \(\chi_{\text{spin}} \sim \text{constant}\) and \(\rho_{ab} \sim T\) after \(\chi_{\text{spin}}\) is suppressed.

What are the dominant mechanisms that govern the \(T\) and \(x\) dependences of \(\chi_{\text{spin}}\)? Since the undoped sample undergoes AFLRO below \(T_{\text{SDW}} = 135\) K, one obvious possibility is that the growth of antiferromagnetic short-range order (AFSRO) suppresses \(\chi_{\text{spin}}\) with decreasing \(T\). However, AFSRO alone cannot account for the \(x\) dependence, because \(\chi_{\text{spin}}\) is smaller for the Co doped samples without AFLRO. In
other words, if we attribute \( T \) and \( x \) dependencies entirely to the effects of AFSRO, we would be led to an unphysical conclusion that the antiferromagnetic spin–spin correlation is stronger in the Co doped superconducting phase than in the undoped phase with AFLRO. Moreover, growth of AFSRO generally results in enhancement of \( 1/T_1 T \) with decreasing \( T_c \), as observed for La\(_{2-x}\)Sr\(_x\)CuO\(_4\)\(^{21}\), but our \( 1/T_1 T \) data contradict with such a scenario as explained below. While AFSRO is very likely to play a significant role in controlling the behavior of \( \chi_{\text{spin}} \), there must be an additional mechanism which suppresses \( \chi_{\text{spin}} \). We will address this issue below.

Before proceeding, we would like to comment briefly on the implications of the systematic line broadening of the NMR lines with doping in Fig. 3.\(^{17}\) Equation (2) implies that the distribution of \( K_{\text{spin}} \) in Fig. 3 reflects that of \( \chi_{\text{spin}} \). Accordingly, the FFT lineshapes in Fig. 3 represent a histogram of the distribution of \( \chi_{\text{spin}} \) in each sample. For example, some parts of the \( x = 0.08 \) sample have \( \chi_{\text{spin}} \) as large (small) as that of the \( x = 0.04 \) (sample, i.e., the local electronic properties are inherently inhomogeneous at a microscopic level. We emphasize that one cannot attribute the present finding to macroscopic inhomogeneity of the Co concentrations. As shown in Fig. 1, the electrical resistivity \( \rho_{ab} \) is very sensitive to phase transitions at \( T_{\text{SDW}} \) and \( T_c \). If the \( x = 0.08 \) crystal had a macroscopic domain with Co 4% doping, for example, we would observe an additional SDW anomaly in the \( \rho_{ab} \) data. We recall that analogous microscopic inhomogeneity was also observed for the hole-doped high \( T_c \) cuprates La\(_{2-x}\)Sr\(_x\)CuO\(_4\).\(^{23,24}\) and understood as the consequence of microscopic patch-by-patch inhomogeneity of the carrier concentration with the typical length scales of \( \sim 3 \) nm. Our results in Fig. 3 show that analogous “patchy” electronic inhomogeneity also exists in Ba(Fe\(_{1-x}\)Co\(_x\))\(_2\)As\(_2\) with comparable length scales.

Additional clues on the nature of spin correlations may be seen in the \( T \) and \( x \) dependencies of \( 1/T_1 T \). We summarize \( 1/T_1 T \) measured at the peak of the NMR lineshapes in Fig. 5. Theoretically, \( 1/T_1 T \) is related to the wave vector integral of the low frequency component of spin fluctuations, \[ \frac{1}{T_1 T} \sim \sum_q |\alpha(q)|^2 \frac{\text{Im} x(q, f)}{f}, \] (3) where \( \text{Im} x(q, f) \) is the imaginary part of the dynamic electron spin susceptibility at the NMR frequency \( f \approx 65 \) MHz, \( |\alpha(q)|^2 = |\alpha \cos(q, a/2) \cos(q, a/2)|^2 \) is the form factor of the transferred hyperfine interaction at the \( ^{75}\)As sites (\( \alpha \) is the lattice constant),\(^{15}\) and the wave vector summation of \( q \) is taken over the first Brillouin zone. The undoped \( x = 0 \) sample does not exhibit a large enhancement of \( 1/T_1 T \) immediately above \( T_{\text{SDW}} = 135 \) K, in agreement with Kitagawa et al.\(^{18}\) There are two reasons for the absence of the signature of critical slowing down. First, the AFLRO is accompanied by a tetragonal to orthorhombic structural phase transition,\(^8\) and the simultaneous magnetic and structural phase transitions are weakly first order.\(^{18}\) Second, since we are applying \( B_{\text{ext}} \) along the \( c \)-axis, the \( ab \)-plane components of the dipole hyperfine fields from Fe moments, as well as the transferred hyperfine fields in eq. (3), cancel out at the location of \( ^{75}\)As sites when spin correlations are commensurate\(^7,8\) with the lattice.

On the other hand, underdoped \( x = 0.02 \) and 0.04 samples show a divergent behavior of \( 1/T_1 T \) due to critical slowing down of spin fluctuations toward \( T_{\text{SDW}} = 100 \) and 66 K, respectively. This strongly suggests that an SDW state, presumably incommensurate with the lattice, emerges below \( T_{\text{SDW}} \) as a result of the second order phase transition. Moreover, we confirmed that the whole NMR line broadens below \( T_{\text{SDW}} \), hence the SDW transition affects the 100% volume of the sample. We will report the complete details elsewhere.

We have not conducted NMR measurements in the concentration range \( x = 0.05–0.07 \). However, the NMR lineshapes of the \( x = 0.04 \) and 0.08 samples are significantly superposed because of the patchy inhomogeneity, and we have found that \( 1/T_1 T \) measured at the higher-intensity position on the lower \( K \) side of the \( x = 0.04 \) is nearly the same as \( 1/T_1 T \) measured at the high intensity position on the higher \( K \) side of the \( x = 0.08 \) crystals (see Fig. 3). These \( 1/T_1 T \) data points measured in the middle between the peaks of \( x = 0.04 \) and 0.08 are plotted in Fig. 5, labeled as the results for the effective concentration of “6%”. The enhancement of \( 1/T_1 T \) toward \( T_c = 22 \) K for “6%” and 8% samples signals the residual effects of low frequency AFSRO at low temperatures, and we conclude that the FeAs layers are on the verge of forming an SDW ground state even for \( x \lesssim 0.08 \).

In contrast, \( 1/T_1 T \) for the slightly overdoped \( x = 0.105 \) levels off after monostonic decrease with \( T \), and exhibits no evidence for the enhancement due to low frequency AFSRO. Equally important to notice is that \( 1/T_1 T \) initially decreases with \( T \) below 300 K even in the underdoped \( x = 0.02 \) and 0.04 samples. We confirmed that \( 1/T_1 T \) at the Co sites in \( x = 0.08 \)\(^{15}\) and \( x = 0.04 \) (not shown) shows qualitatively the same behavior as at \( ^{75}\)As sites; hence the present results are not the consequence of accidental cancellation of the hyperfine fields at \( ^{75}\)As sites. Recalling that the uniform (i.e., \( q = 0 \)) spin susceptibility \( \chi_{\text{spin}} \) is also suppressed below 300 K for all concentrations, we conclude that the low energy spin excitations are suppressed with decreasing \( T \) except near \( T_{\text{SDW}} \), i.e., Ba(Fe\(_{1-x}\)Co\(_x\))\(_2\)As\(_2\) exhibits spin pseudo-gap behavior for a broad concentration range. We note that analogous pseudo-gap behavior was first observed...
in LaFeAsO$_{1-x}$F$_{x}$$_{0.11}$ ($T_c = 28$ K) using $^{19}$F NMR.\textsuperscript{25} Although the mechanism behind the spin pseudo-gap behavior is unclear at this time, it is interesting to realize that the $J_1 - J_2$ Heisenberg model, which is considered a viable starting point for the theoretical description of iron-pnictides,\textsuperscript{26} is indeed expected to exhibit a gapped behavior in NMR properties.\textsuperscript{27} On the other hand, if we consider Fe spins as localized moments described by the $J_1 - J_2$ Heisenberg model, we expect that the exchange narrowing in the intermediate temperature range $T \sim 1.2/2$ or higher. No evidence for such localized moment behavior is seen in Fig. 5 at least up to 300 K.

How does electron doping affect the spin pseudo-gap? In Fig. 4, we fit the temperature dependence of $K$ by assuming an empirical activation formula, $K = A + B \times \exp(-\Delta_{PG} / k_B T)$, where $A$ and $B$ are constants. The best fit yields $\Delta_{PG} / k_B \simeq 710, 570, 520, \text{ and } 490$ K for $x = 0, 0.04, 0.08, \text{ and } 0.10$. It is not clear whether the apparent systematic decrease of $\Delta_{PG}$ with doping is intrinsic, because we found that the fit is extremely sensitive to the choice of the constant term $A$ and the uncertainty of $\Delta_{PG}$ is as large as ~30%.

For LaFeAsO$_{1-x}$F$_x$, analogous fit of $1/T_1 T$ or $K$ yields $\Delta_{PG} / k_B \sim 160$ K for $x > 0.10$.\textsuperscript{9,19,28}

In order to gain insights into the essential physics of the suppression of low energy spin excitations without making any assumptions, we create the contour map of equal values of $K$ or $1/T_1 T$ in Fig. 2. First, let us focus our attention on the black dotted lines representing the equal value contours of $K$. For example, upon cooling, $K$ decreases to 0.28% at $\sim 250, \sim 221, \text{ and } \sim 164$ K for $x = 10.5, 8, \text{ and } 4$ doped sample, respectively. We can clearly observe that $K$, hence $\chi_{\text{spin}}$, is smaller for lower $T$ and larger $x$. Let us turn our attention to the blue dashed lines representing the equal value contours of $1/T_1 T$. As shown in Fig. 5, the growth of low frequency spin fluctuations enhances $1/T_1 T$ toward $T_{\text{SDW}}$, and $1/T_1 T = 0.4 s^{-1} K^{-1}$ is reached at 130, 87, and 30 K for $x = 2, 4, \text{ and } “6”$, respectively. Notice that the residual tendency toward forming the SDW ground state barely disappears at the optimum doping $x_c \sim 0.08$ with the highest $T_c = 22$ K. Thus we conclude that the “superconducting dome” appears right on top of the quantum critical point near $x_c \sim 0.08$ where the tendency toward forming the SDW phase disappears. We note that the disappearance of the low frequency components of spin fluctuations does not mean that spin fluctuations diminish all together. In fact, the pseudo-gap behavior suggests that the over all spectral weight of spin fluctuations may be shifted to higher energies.

To summarize, we measured the in-plane resistivity, intrinsic spin susceptibility, and low frequency spin dynamics of Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$. We also established the electronic phase diagram, and demonstrated that the quantum critical point between the SDW and superconducting phases is located near the optimum superconducting concentration $x_c = 8\%$.
